⁴ **Abstract**

This technical note presents the derivation, validation, and application of a *three-node torsional spring* (3NTS) element for the analysis of bar-linked, reconfigurable structures. The 3NTS element assigns rotational stiffness to a joint (node) of two axial force members (bars) in truss-like assemblies. This element avoids the use of rotational degrees of freedom by recasting its resisting moment into equivalent nodal forces, which are consistent with global equilibrium, thereby keeping the model size compact and computationally efficient. The 3NTS is integrated into standard non-linear solvers to simulate large-displacement response and validated against analytical solutions of two benchmark examples: the simplest 3NTS structure and the buckling of a vertical column. We further apply the framework to a reconfigurable truss structure from our previous work to illustrate potential functional use cases and outline its broader applicability to metamaterials, kirigami systems, and biomechanical assemblies. An open-source matrix structural analysis tool implementing the 3NTS and axial force members is made available with this note.

¹ **1. Introduction**

² Over the past century, structural element formulations have evolved to capture nonlinearity
³ and connection flexibility, enabling accurate modeling of practical structures [1]. However, the
⁴ support for modeling joint rotational stiffness within truss-like structures using a torsional (or coil)
⁵ spring remains limited, especially in formulations with minimal degrees of freedom (DOF) and
⁶ high computational efficiency.

⁷ Joint rotational stiffness is crucial in applications where controlled joint rotation influences the
⁸ global structural behavior. Some examples include reconfigurable linkages and robotic arms that
⁹ rely on programmed hinge stiffnesses [2–5], biomechanics where joint stiffness affects function [6,
¹⁰ 7], origami-inspired mechanisms where crease stiffness governs panel folding [8–10], and semi-
¹¹ rigid connections in lattice structures and metamaterials that store and release energy to achieve
¹² functional reconfiguration [11–13].

¹³ A typical workaround for joint rotational stiffness in two-dimensional bar-linked structures in-
¹⁴ volves the use of semi-rigid joints. These semi-rigid joints introduce a short beam element (3
¹⁵ DOFs per node) at the joint and impose rotational stiffness by assigning ad-hoc stiffness values to
¹⁶ the node's rotational degree of freedom [14–17]. While serviceable, this approach may yield spu-
¹⁷ rious results if the user-chosen stiffness value is not representative of the structural behavior [18].
¹⁸ Furthermore, it increases the computational complexity by inflating the model, as representing a
¹⁹ single joint by a beam segment requires six DOFs over the two required for a bar-bar joint in
²⁰ two-dimensional space.

²¹ We address this gap by introducing a *three-node torsional spring (3NTS)* element to model a
²² joint's rotational resistance within bar-linked structures. The 3NTS element consists of two elastic
²³ axial force members (bars) joined at an intermediate node, which hosts a torsional spring of lumped

1 rotational stiffness K_T [Nm/rad] (Fig. 1). When the relative angle between the bars (α) changes, the
2 spring develops a resisting moment that is recast as equivalent nodal forces consistent with global
3 equilibrium. Since α is a function of the coordinates of the three nodes, the 3NTS requires only
4 six translational DOFs for its representation in a two-dimensional space. Consequently, a two-
5 dimensional bar-linked assembly using the 3NTS elements has the *same* global DOF count as an
6 equivalent spring-less truss structure. Thus, by avoiding rotational DOFs, this formulation yields
7 a compact model with improved computational efficiency over ad-hoc joint rotational stiffness
8 workarounds.

9 The proposed 3NTS element provides a minimal, first-principles representation of a joint
10 with rotational stiffness, which the current literature lacks. Furthermore, it decouples the joint's
11 moment-rotation behavior from axial force-displacement effects by allowing standard bar elements
12 to handle the axial and positional effects. This concept draws on the bar and hinge origami mod-
13 els [19–22] where three-dimensional rotational hinges capture crease folding and sheet bending.
14 Here, we distill that concept and apply it to a two-dimensional case to assess the global struc-
15 tural behavior of bar-linked reconfigurable structures with torsional springs. We believe that this
16 reduced-order formulation will aid in the exploration and efficient simulation of system behaviors
17 in biomechanics, robotics, compliant mechanisms, planar metamaterials, and kirigami lattices.

18 The remainder of the note is organized as follows. Section 2 derives the torsional spring stiff-
19 ness matrix. Section 3 validates the simulated response of the torsional spring against analytical
20 solutions of benchmark examples. Section 4 illustrates the potential application of the developed
21 analysis program to reconfigurable bar-linked structures. Finally, Section 5 summarizes the con-
22 tributions of this work.

2. Stiffness matrix of a three-node torsional spring element

The stiffness matrix of a two-dimensional three-node torsional spring is derived from the spring's constitutive law by evaluating the Jacobian and Hessian of its strain energy. The torsional spring unit shown in Fig. 1 consists of three nodes 1, 2, and 3 with undeformed coordinates (X_1, Y_1) , (X_2, Y_2) , and (X_3, Y_3) , respectively. Bar 1 connects nodes 1 and 2, and bar 2 connects node 2 and 3. Each bar behaves as an axial-force member. A torsional spring of stiffness K_T is located at node 2, producing moment contributions only when the relative angle between bars 1 and 2 changes. The nodal coordinates in the deformed configuration are (x_1, y_1) , (x_2, y_2) and (x_3, y_3) .

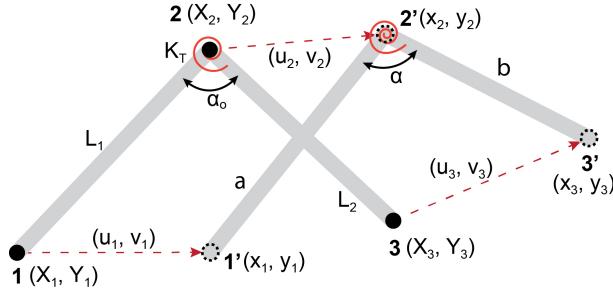

Fig. 1. A schematic representation of the three-node rotational spring unit depicting the nodal displacements.

8

Let the position vectors in the undeformed and deformed configurations be $R_1 = [X_1, Y_1]^\top$, $R_2 = [X_2, Y_2]^\top$, $R_3 = [X_3, Y_3]^\top$, and $r_1 = [x_1, y_1]^\top$, $r_2 = [x_2, y_2]^\top$, $r_3 = [x_3, y_3]^\top$, respectively. The global nodal coordinate vectors are expressed as $R = [R_1^\top, R_2^\top, R_3^\top]^\top$ and $r = [r_1^\top, r_2^\top, r_3^\top]^\top$, and the corresponding displacement vector is defined as $u = r - R$.

¹ 2.1. Torsional spring constitutive law

² The strain energy of a linearly elastic three-node torsional spring is expressed as

$$U(\alpha) = \frac{1}{2} K_T (\alpha - \alpha_o)^2, \quad (1)$$

³ where K_T is the spring's rotational stiffness, $\alpha = \alpha(r)$ denotes the relative angle between the two
⁴ connected bars as a function of the global nodal coordinate vector r , and $\alpha_o = \alpha(R)$ represents
⁵ the undeformed (rest) angle of the spring, defined with respect to the undeformed global nodal
⁶ coordinate vector R .

⁷ The internal nodal force vector is obtained by differentiating the strain energy with respect to
⁸ the displacement vector:

$$F_{\text{int}} = \frac{\partial U}{\partial u} = \frac{\partial U}{\partial \alpha} \frac{\partial \alpha}{\partial u}. \quad (2)$$

⁹ Recalling that the spring's reference configuration R is constant, gradients with respect to the
¹⁰ displacement vector are equivalent to those with respect to the deformed coordinates, i.e., $\partial u = \partial r$.
¹¹ Defining the gradient of the relative angle as $\nabla \alpha = \partial \alpha / \partial u = \partial \alpha / \partial r$ and the moment generated
¹² by the spring as $M = \partial U / \partial \alpha = K_T (\alpha - \alpha_o)$, the internal force can be expressed as

$$F_{\text{int}} = M \nabla \alpha = K_T (\alpha - \alpha_o) \nabla \alpha. \quad (3)$$

¹³ The tangent stiffness matrix is obtained by differentiating the internal force with respect to the
¹⁴ deformed global nodal coordinates:

$$K_{\text{spr}} = \frac{\partial F_{\text{int}}}{\partial r} = \frac{\partial}{\partial r} (M(r) \nabla \alpha(r)) = M(r) \nabla^2 \alpha(r) + \nabla M(r) \nabla \alpha(r)^\top. \quad (4)$$

¹⁵ Because $M = K_T (\alpha - \alpha_o)$, it follows that $\nabla M = K_T \nabla \alpha$. Substituting these relations into Eq. 4
¹⁶ yields the final expression for the element stiffness matrix:

$$K_{\text{spr}} = K_T \left[(\nabla \alpha) (\nabla \alpha)^\top + (\alpha - \alpha_o) \nabla^2 \alpha \right]. \quad (5)$$

¹ 2.2. Relative angle between the bars

² Let the vectors along bars 1 and 2 be defined as $a = r_1 - r_2$ and $b = r_3 - r_2$, where $r_i = [x_i, y_i]^\top$ are
³ the nodal position vectors in the deformed configuration. Define the 90° clockwise rotation matrix
⁴ N such that, for any vector v , the product Nv represents a rotation of v by $+90^\circ$. Furthermore, the
⁵ property $N = -N^\top$ holds true.

$$N = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix} \quad (6)$$

⁶ The cosine and sine of the relative angle α between bars 1 and 2 are then expressed as

$$\begin{aligned} C &= a \cdot b = \|a\| \|b\| \cos(\alpha), \\ S &= a^\top Nb = \|a\| \|b\| \sin(\alpha). \end{aligned} \quad (7)$$

⁷ Hence, the relative angle α is obtained as

$$\alpha = \tan^{-1}\left(\frac{S}{C}\right). \quad (8)$$

⁸ It is important to note that this expression alone does not capture the full range of possible rotations,
⁹ as the `atan2` function in MATLAB returns values in the interval $[-\pi, \pi]$. To obtain a continuous
¹⁰ measure of rotation in the range $[0, 2\pi]$, the computed angle is modified as

$$\alpha = \text{mod}(\alpha, 2\pi), \quad (9)$$

¹¹ under the assumption that the torsional spring does not undergo self-overlapping deformations.

¹² 2.3. Derivatives of bar vectors and auxiliary quantities

¹³ The gradient of α with respect to the global nodal coordinates can be derived by differentiating
¹⁴ Eq. 8. Using the chain rule, we have

$$\nabla \alpha = \frac{1}{1 + (S/C)^2} \left(\frac{C \nabla S - S \nabla C}{C^2} \right) = \frac{C \nabla S - S \nabla C}{C^2 + S^2} = \frac{C \nabla S - S \nabla C}{\|a\|^2 \|b\|^2}. \quad (10)$$

¹ To evaluate Eq. 10, the derivatives of vectors a , b , and the scalar quantities C and S with respect
² to the nodal coordinates are required. These are given by

$$\begin{aligned}\frac{\partial a}{\partial r_1} &= \mathbf{I} & \frac{\partial a}{\partial r_2} &= -\mathbf{I} & \frac{\partial a}{\partial r_3} &= \mathbf{0} \\ \frac{\partial b}{\partial r_1} &= \mathbf{0} & \frac{\partial b}{\partial r_2} &= -\mathbf{I} & \frac{\partial b}{\partial r_3} &= \mathbf{I} \\ \frac{\partial C}{\partial r_1} &= b & \frac{\partial C}{\partial r_2} &= -(a + b) & \frac{\partial C}{\partial r_3} &= a \\ \frac{\partial S}{\partial r_1} &= Nb & \frac{\partial S}{\partial r_2} &= N(a - b) & \frac{\partial S}{\partial r_3} &= -Na\end{aligned}\quad (11)$$

³ 2.4. Closed-form expression for gradient of relative angle

⁴ Substituting Eq. 11 into Eq. 10 and applying the vector identity $(x \cdot y)Ny - (x^\top Ny)y = \|y\|^2Nx$
⁵ the gradient components of α can be expressed in compact form as:

$$\begin{aligned}\nabla\alpha_{11} &= \frac{\partial\alpha}{\partial r_1} = \frac{C(\partial S/\partial r_1) - S(\partial C/\partial r_1)}{\|a\|^2\|b\|^2} = \frac{(a \cdot b)Nb - (a^\top Nb)b}{\|a\|^2\|b\|^2} = \frac{Na}{\|a\|^2} \\ \nabla\alpha_{21} &= \frac{\partial\alpha}{\partial r_2} = \frac{C(\partial S/\partial r_2) - S(\partial C/\partial r_2)}{\|a\|^2\|b\|^2} = \frac{(a \cdot b)N(a - b) + (a^\top Nb)(a + b)}{\|a\|^2\|b\|^2} = \frac{Nb}{\|b\|^2} - \frac{Na}{\|a\|^2} \\ \nabla\alpha_{31} &= \frac{\partial\alpha}{\partial r_3} = \frac{C(\partial S/\partial r_3) - S(\partial C/\partial r_3)}{\|a\|^2\|b\|^2} = \frac{(a \cdot b)(-Na) - (a^\top Nb)a}{\|a\|^2\|b\|^2} = -\frac{Nb}{\|b\|^2}\end{aligned}\quad (12)$$

(13)

⁶ These three 2×1 vectors together form the full 6×1 gradient vector $\nabla\alpha$.

¹ 2.5. Hessian of the relative angle

² The Hessian matrix $\nabla^2\alpha$ is of size 6×6 and consists of nine 2×2 sub-blocks corresponding to
³ the second derivatives of α with respect to the nodal coordinates. The sub-blocks are expressed as

$$\begin{aligned}\mathbf{H}_{11} &= \frac{1}{\|a\|^2}N - \frac{2}{\|a\|^4}(Na)a^\top \\ \mathbf{H}_{22} &= \frac{1}{\|a\|^2}N - \frac{2}{\|a\|^4}(Na)a^\top + \frac{2}{\|b\|^4}(Nb)b^\top - \frac{1}{\|b\|^2}N \\ \mathbf{H}_{33} &= \frac{2}{\|b\|^4}(Nb)b^\top - \frac{1}{\|b\|^2}N \\ \mathbf{H}_{12} = \mathbf{H}_{21}^\top &= \frac{2}{\|a\|^4}(Na)a^\top - \frac{1}{\|a\|^2}N \\ \mathbf{H}_{13} = \mathbf{H}_{31}^\top &= \mathbf{0} \\ \mathbf{H}_{23} = \mathbf{H}_{32}^\top &= \frac{1}{\|b\|^2}N - \frac{2}{\|b\|^4}(Nb)b^\top\end{aligned}\tag{14}$$

⁴ Thus, we have all the necessary information to form the stiffness matrix for a three-node torsional
⁵ spring and use it in matrix structural analysis solvers.

⁶ **3. Validation of the three-node torsional spring element**

⁷ In this section, we validate the derived stiffness matrix of the torsional spring element by com-
⁸ paring the simulated behavior of two torsional-spring fitted bar-linked structures with their respec-
⁹ tive analytical solutions. The torsional spring element is implemented alongside linearly elastic
¹⁰ axial bar elements within non-linear structural analysis solvers [23] to facilitate large-deformation
¹¹ simulations of torsional-spring fitted bar-linked structures. The two examples presented herein
¹² demonstrate the element's capability to simulate large-deformation responses, evaluate strain en-
¹³ ergies stored in each structural element, and reproduce buckling behavior in collinear bar systems
¹⁴ under compression.

1 3.1. Comparing analytical and simulated behavior of the simplest three-node torsional spring
 2 structure

3 The simplest bar-linked structure with a three-node torsional spring is the element itself, as
 4 shown in Fig. 2(a). Nodes A and B are fixed supports, while node C is free. Bars connecting
 5 nodes A-B and B-C have a Young's modulus $E = 3 \times 10^6$ Pa, cross-sectional area $A = 0.5 \text{ m}^2$,
 6 and length $L = 1 \text{ m}$. A torsional spring with stiffness $K_T = 50 \text{ Nm/rad}$ is located at node B. A
 7 gradually increasing external load P is applied at node C in the positive Y-direction.

8 The analytical response of this structure can be obtained using potential energy analysis. When
 9 subjected to the applied load P , the bar connecting nodes B and C rotates by an angle θ and
 10 elongates by ΔL . The elongation is induced by the component of the applied load along the bar's
 11 axis and is expressed as $\Delta L = (PL/EA) \sin(\theta)$. In this deformed state, the total potential energy of
 12 the structure is

$$U = \frac{1}{2}K_T\theta^2 - PL \sin(\theta) - \frac{P^2L}{2EA} \sin^2(\theta). \quad (15)$$

13 The equilibrium condition is obtained by setting $\partial U / \partial \theta = 0$, which yields the following expression
 14 for the applied load P :

$$P = \frac{-AEL \cos(\theta) \pm AE \sqrt{\frac{L \cos(\theta)}{EA} (4K_T\theta \sin(\theta) + AEL \cos(\theta))}}{2L \sin \theta \cos \theta}. \quad (16)$$

15 The corresponding vertical displacement of node C due to the applied load becomes $\Delta = (L +$
 16 $\Delta L) \sin(\theta)$.

17 Figure 2 (b) compares the analytical and simulated load-displacement responses of the simple
 18 three-node torsional spring structure. The two curves show excellent agreement over the entire
 19 range of deformation. The load increases from zero and appears to approach infinity asymptoti-
 20 cally as the bar rotates from 0° to 90° . In reality, the load does not become infinite. Throughout the

1 range of deformation, the applied load is primarily resisted by the torsional spring. As the angular
2 rotation of the bar approaches 90° , however, the load begins to increase approximately in propor-
3 tion to the axial stiffness of the bar, EA/L , as both the bar and the spring resist the external load.
4 Because this axial stiffness is several orders of magnitude greater than the torsional spring stiffness,
5 the overall response visually appears to asymptote toward infinity in the load-displacement plot.
6 Furthermore, the excellent alignment between the work done by the external load and the cumula-
7 tive strain energy stored in each element type, as shown in Fig. 2 (c), confirms energy balance and
8 validates the correct implementation of the torsional spring element within the non-linear solver
9 framework.

10 *3.2. Comparing analytical and simulated buckling behaviour of a vertical column structure*

11 The vertical column structure shown in Fig. 2 (d) consists of two bars with a torsional spring
12 element at the central joint. The bottom end of the column is fixed, while the top end is a roller
13 support that restrains horizontal motion but allows vertical movement. The analytical relationship
14 between the load, P and bar rotation θ can be obtained using potential energy analysis as

$$P = \frac{2K\theta}{L \sin(\theta)}. \quad (17)$$

15 The structure becomes unstable when the applied load reaches the critical value $P = 2K/L$. There-
16 after, the column undergoes progressive deformation until each bar rotates by $\theta = \pi/2$, at which
17 stage the load reaches $P = \pi K/L$, representing a fully folded configuration. The vertical displace-
18 ment of the roller end beyond instability can be expressed as $\Delta = 2L(1 - \cos(\theta))$. It should be noted
19 that the potential energy analysis assumes rigid bars, while the non-linear solvers model the bars
20 as linearly elastic. Consequently, slight differences are expected in the analytical and simulated
21 buckling behavior of the vertical column.

22 In the simulation, the bars have a Young's modulus $E = 3 \times 10^9$ Pa, cross-sectional area

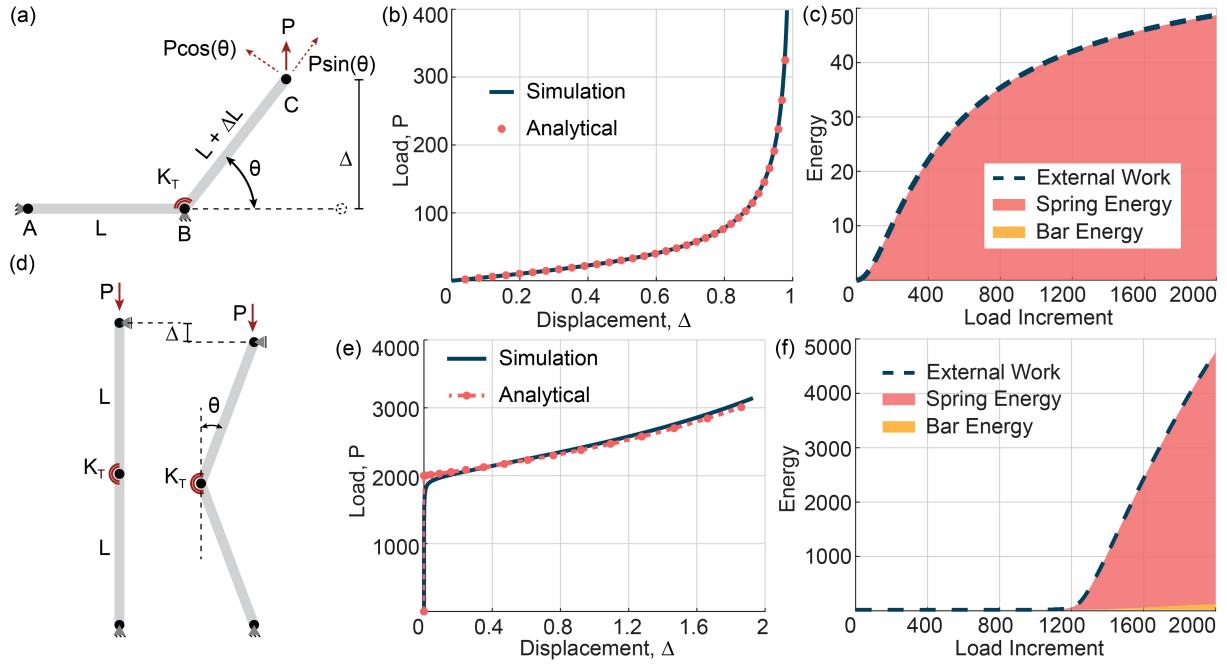

Fig. 2. Validation of the simulated behavior of bar-linked structures with torsional spring elements against their respective analytical solutions. (a) Simplest structure with a torsional spring element; (b) Comparison of analytical and simulated load–displacement responses for the structure in (a); (c) Simulated external work and stacked internal strain energies (spring and bars) over load increments for the structure in (a); (d) Buckling of a bar-linked vertical column comprising of two bars and a torsional spring element at the central joint; (e) Comparison of analytical and simulated load–displacement responses for the structure in (d); (f) Simulated external work and stacked internal strain energies (spring and bars) over load increments for the structure in (d).

¹ $A = 1 \text{ m}^2$, bar lengths $L = 1 \text{ m}$, and torsional spring stiffness $K_T = 1000 \text{ Nm/rad}$. A minor
² geometric imperfection is introduced at the free node to trigger the buckling behaviour. As shown
³ in Fig. 2(e), the simulated structure exhibits instability at a load slightly lower than predicted
⁴ analytically, due to elastic bar deformations and non-ideal buckling triggered with a geometric
⁵ imperfection. After the onset of buckling, the load continues to increase till the bars rotate by
⁶ $\theta = \pi/2$. Overall, the simulated load-displacement curve agrees well with the analytical prediction,
⁷ capturing the same deformation trend and load magnitude, with minor deviations attributed to
⁸ elastic bar effects and accumulated numerical drift at large displacements. Moreover, the close
⁹ agreement between the work done by external loads and internal strain energies shown in Fig. 2(f)
¹⁰ validates the torsional spring element behaviour within the non-linear solvers.

¹¹ **4. Application to reconfigurable bar-linked structures**

¹² With the torsional spring element validated, the developed analysis program can now be ex-
¹³ tended to study load requirements for actuation and functional applications of reconfigurable bar-
¹⁴ linked structures. Previous work by the authors introduced a systematic method to generate recon-
¹⁵figurable trusses from existing static truss designs and demonstrated their stability under design
¹⁶ loading conditions. These reconfigurable trusses can be fitted with torsional springs at their re-
¹⁷configurable joints, enabling them to serve as functional systems capable of storing and releasing
¹⁸ energy during load reversals.

¹⁹ The torsional spring implementation within the non-linear solver facilitates the simulation of
²⁰ load-displacement responses in such reconfigurable bar-linked systems. Incorporating torsional
²¹ springs into these structures allows for the study of impact energy storage through spring strain
²² energy, provided that the springs are locked after reaching their maximum deformation. This
²³ configuration also enables the evaluation of the stiffness associated with rotational joints and the

estimation of actuation forces required to deploy or reconfigure the structure. As a preliminary

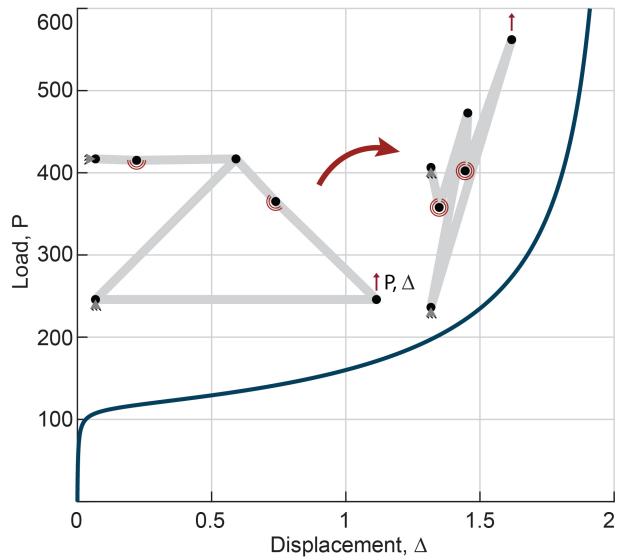

Fig. 3. Load analysis of the actuation of a reconfigurable cantilever truss

1 demonstration, a reconfigurable truss structure from the authors' earlier work is analyzed here to
 2 illustrate the potential application the developed analysis program. The reconfigurable cantilever
 3 truss shown in Fig. 3 remains force-stable when loaded along the negative-Y direction. When the
 4 direction of loading is reversed to induce reconfiguration, the developed analysis program can be
 5 used to evaluate the load-displacement response of the structure for various spring stiffnesses. Be-
 6 tween the two orientations shown in Fig. 3, an actuation force of approximately 600 N was required
 7 to achieve reconfiguration. The resulting load-displacement curve reflects characteristics similar to
 8 those observed in the validation examples—exhibiting both spring deformation and buckling be-
 9 havior—and also illustrates the amount of energy stored within the system due to the applied load.
 10 This stored energy can be harnessed for functional purposes when the structure is constrained from
 11 returning to its original configuration. With further development, the analysis framework may also
 12 enable sequential release of individual torsional springs, providing a mechanism for controlled or
 13

¹ rapid deployment of reconfigurable structures.

² 5. Concluding remarks

³ This technical note presented the formulation of a three-node torsional spring element stiffness
⁴ matrix and validated its accuracy through comparison with analytical solutions of two benchmark
⁵ examples. The torsional spring element successfully captured large-deformation responses and
⁶ the onset of buckling in spring-fitted bar-linked structures. Finally, an example was included to
⁷ demonstrate the capability of the developed analysis program to simulate actuation in reconfig-
⁸ urable bar-linked structures equipped with torsional springs. This example previews the program's
⁹ potential to explore functional use cases of reconfigurable bar-linked structures. The solver imple-
¹⁰ mentation is made available as a matrix structural analysis program accompanying this note.
